Chapter 46

Presurgical evaluation and outcome of epilepsy surgery in childhood

J. HELEN CROSS

UCL Institute of Child Health, Great Ormond Street Hospital for Children NHS Trust, London, and Young Epilepsy, Lingfield

Introduction

Surgery in the management of children with epilepsy is not new. Murray Falconer, a neurosurgeon at the Maudsley Hospital, recognised that children as well as adults may benefit from resective surgery, but the age range of his patients did not include the very young. Traditionally, focal seizures have been more difficult to diagnose in the young child, both clinically and electrographically, and a focal onset to seizures may not be readily apparent. However, the advent of magnetic resonance imaging (MRI), with the increased detection of structural focal brain abnormality, has opened up the possibility of surgery at an earlier stage in the natural history of childhood epilepsy.

Selection criteria

There are several points to discuss when considering whether surgery may be more beneficial earlier rather than later. Many adults presenting for resective surgery have a history of seizures arising from early childhood, and have been through multiple antiepileptic drugs (AEDs). Prior to the recognition of different types of epilepsy there was concern that children may ‘grow out’ of epilepsy but with the use of the classification of the epilepsies the syndromes with a relatively good prognosis can now be recognised at an early stage, and when these have been excluded the focal epilepsies are among the most drug resistant. Chronic epilepsy is not without psychosocial morbidity however; the Oxford study of 100 children with temporal lobe epilepsy demonstrated that at least one-third were not leading an independent life in adulthood. Early surgery may therefore reduce the morbidity associated with frequent seizures through the teenage years.

There are specific issues related to children that need to be considered in the discussion of the early surgical treatment of epilepsy. The definition of ‘medically intractable epilepsy’ in adult practice is often defined as epilepsy which has not responded to at least three AEDs over at least a three-year period. Although in the older child attending normal school this may have relevance, in the young child experiencing recurrent seizures, and where compromise to developmental progress has been demonstrated, it is likely that a greater number of drugs will have been tried over a lesser period of time. Perhaps the most appropriate definition of intractability in children is ‘inadequate seizure control in spite of appropriate medical therapy’ with no particular timescale. This has been addressed in the recent ILAE report on drug resistance, where drug-resistant epilepsy is now defined as ‘a failure of adequate trials of two tolerated and appropriately chosen and used AED schedules, whether as monotherapies or in combination, to achieve sustained seizure freedom’.

The whole issue of what is ‘intractability’ in childhood remains a question for debate, and we lack tools for prediction of prognosis. We know from epidemiological studies that poor prognostic indicators are early onset of seizures, poor response to first-line medication, focal
seizures, and a demonstrable structural lesion. We can therefore only assume that with early
cessation of seizures, we allow the child to achieve its optimal learning potential.
Longitudinal studies post surgery are lacking, not least because of a lack of standardised tools
to assess cognitive performance across all ages. However, at the very least, children have
been demonstrated to maintain their developmental trajectory post surgery, that would
otherwise have been lost, and recent data looking at children who have undergone early
surgery suggests improved developmental outcome may be achieved⁴. More recent data
suggest greater benefits may be achieved in the longer term, with studies demonstrating
greater developmental gains in seizure-free patients the longer time passes after surgery⁵,⁶.

The group of children for whom surgery is considered is also more diverse than the adult
group. A significant number will have developmental compromise, in whom an improved
quality of life is a priority rather than solely freedom from seizures (although this is obviously
a consideration). Assessment for surgery should therefore be in the context of a complex
epilepsy service⁷. The need for concentration of resources required for epilepsy surgery in
children has recently been recognised in England and Wales with the designation of four
nationally funded centres as part of the Children’s Epilepsy Surgery Service (CESS).

Types of surgery

The types of surgery performed in children do not differ a great deal from those in adults, but
the proportion of each procedure carried out, and the type of patient on which it is performed,
both vary. An international survey of 458 operations performed in 450 children over a 12-
month period (2004) revealed two-thirds (63%) to be hemispherectomy or multilobar
resections (Figure 1). Unilobar resections or lesionectomies were undertaken in 30%, with
only a very small number of functional procedures being performed⁸. Furthermore, 63% were
due to underlying developmental as opposed to acquired pathology⁵.

Focal resection involves removal of a small part or the whole of one lobe. Seizures should be
shown to arise from one area of the brain, the removal of which will not interfere significantly
with function. Hemispherectomy is considered in children with a pre-existent hemiparesis (in
the absence of progressive disease) with a demonstrable structural abnormality of the
contralateral hemisphere. In a small number of children with Rasmussen’s syndrome (chronic
encephalitis involving one cerebral hemisphere) surgery may be considered prior to the
development of a dense hemiparesis. This may also be considered in children with Sturge-
Weber syndrome with early onset seizures and recurrent status epilepticus.

Corpus callosotomy is considered in children with ‘drop’ attacks, whatever the seizure type
(e.g. akinetic, myoclonic, tonic). This procedure is unlikely to have any effect on other seizure
types, and a child is highly unlikely to be rendered seizure free by the procedure. Subpial
transection has been considered for children with acquired epileptic aphasia (Landau-
Kleffner syndrome), although more often in combination with resection where the seizure
focus lies within eloquent cortex. The procedure involves transection of transverse fibres,
theoretically leaving vertical functional tracts intact. In Landau-Kleffner syndrome the
technique has been performed over Wernicke’s area of the driving hemisphere (determined
by presurgical investigation) under electrocorticographic guidance. Data on outcome and
relative benefits of this procedure compared to medical treatment are limited, although recent
data suggest no benefit of surgery over and above the natural history of the condition.

The presurgical evaluation

In all types of resective epilepsy surgery the presurgical evaluation aims to establish the area from which seizures arise, and to determine that removal of that area will not further compromise the child, i.e. the seizure focus to be resected does not lie in functionally critical cortex. In all children this must start with full clinical evaluation, not only to detail full seizure and AED history, but also to determine the degree of any clinical neurological abnormality, and whether the expectations of the family are realistic. It is current practice at Great Ormond Street to use a predominantly non-invasive presurgical work-up, and the following outlines our current investigation protocol. It is important to emphasise that no investigation provides all the information that is required, and a multidisciplinary approach is mandatory. The extent of investigations required in each individual case will depend in part on the underlying cause, and certainty on concordance. The relative role of technologies available was recently reviewed by the ILAE9.

Focal resection
Optimised MRI (with extensions of this in temporal lobe epilepsy such as T2 relaxometry of the hippocampi, volumetrics), including a 3D data set to determine any evidence of focal brain abnormality. In children aged three months to two years however areas of neocortical abnormality may not be apparent in view of incomplete myelination. It is therefore important to consider review of early imaging, as well as repeat imaging with a suitable time interval. Such abnormalities however may be related to functional abnormality with ictal and inter-ictal EEG, as well as ictal and inter-ictal SPECT or inter-ictal PET in selected cases. Magnetoencephalography may also be useful in image-negative older children. In addition, language and/or motor fMRI may be useful in older children where the seizure focus lies close to eloquent cortex.

Hemispherectomy
MRI to assess the extent and pathology of the structural abnormality of the abnormal hemisphere, as well as review of the ‘normal’ side to make sure there is no evidence of more widespread disease. EEG, ictal and inter-ictal, for lateralisation. Bilateral inter-ictal EEG abnormalities do not preclude consideration for surgery10,11.

Functional procedures

Corpus callosotomy. Clinical history is the main assessment tool, not only to determine seizure type and frequency but to determine social goals. MRI and EEG to determine no evidence of focal disease.

Subpial transection. The investigation of children with Landau-Kleffner syndrome is specific to determining which side may be responsible, and therefore whether surgery can be considered. MRI is performed to exclude a structural brain abnormality. EEG in various forms of sophistication (awake, sleep, possibly ictal, under methohexitone suppression, along with magnetoencephalography) provides the majority of information required.

The role of neuropsychology
Since early pathologies often result in reorganisation of function, the major goal of neuropsychological evaluation is to determine lateralisation and focal representation of function. As in adults, cognitive evaluation predominantly involves assessment of core functions such as intelligence, memory, language, reading and writing. The sodium amylobarbitone (amytal) or WADA procedure has a useful role in determining abnormal language representation in adults who may have suffered congenital or early insult to the left hemisphere. It can also be used to assess memory function prior to surgery, to reduce the risk
of an amnesic syndrome. However developments in functional MRI, assessed in combination with full neuropsychology assessment in experienced hands, mean that the WADA test is now rarely performed for assessment of language in children, particularly in the evaluation for temporal resection.

The role of invasive monitoring

Despite the improved techniques in non-invasive presurgical evaluation, there remains a small proportion of children who benefit from invasive EEG monitoring, whether with subdural grids with or without depth electrodes or in stereo EEG. These are children in whom there is concern that the seizure focus lies within a functionally eloquent area, in children with extratemporal epilepsy in whom all data are concordant but there is no structural abnormality on MRI, and those in whom data are suggestive of a single focus but there may be some doubt.

The role of neuropsychiatry

The exact aims of surgery require discussion to review whether expectations on the part of the patient and family are realistic. This has particular relevance in childhood, as the group under consideration is clinically heterogeneous, and outcome aims are diverse. In particular, in a young child with severe developmental delay and extremely frequent seizures, the aims of surgery may be more related to improved developmental progress and quality of life with,

of course, a reduction of seizures. An older child in normal school is more likely to be seeking seizure freedom and a greater independence. Other associated issues must also be addressed, such as behaviour and any realistic appreciation of change that is unlikely to be predictable. A contract between the professionals and family is desirable prior to the surgical decision.

Outcome

Outcome of epilepsy surgery should be measured not only in terms of seizure freedom, but also in terms of development, neuropsychology, behaviour and quality of life. Seizure freedom is quoted most often in outcome studies no doubt as it is the easiest to determine. Large post-surgical series have shown seizure freedom in 40–87%12-14 (Table 1) related more to the underlying pathology than age at onset of seizures, age at surgery, duration of epilepsy or procedure performed, with better outcome seen with acquired as opposed to developmental pathology. Medication reduction is often an aim of parents, and cannot be guaranteed. Around 50% are successfully weaned from AEDs; a recent European collaborative study demonstrated an early wean did not provoke a recurrence that was not inevitable18.

With focal resection, the degree of epileptogenic tissue removed is a major determinant of seizure outcome, although the degree to which this can be achieved is also related to the underlying pathology. There is some evidence that the outcome following surgery for developmental lesions may deteriorate with time, that is the likelihood of seizure freedom is less in the longer as opposed to the short term, but that outcome with such lesions may be better with earlier surgery14. The lesser likelihood of seizure control however does not preclude consideration, providing the aims of surgery are realistic and clearly identified preoperatively. Many children are also likely to achieve a substantial reduction in seizure frequency13-15 with a reduction in anticonvulsant requirement.

Developmental outcome has been reported as improved following surgery in many studies but has been difficult to quantify, particularly in the very young, as outlined above. As a consequence it is important to obtain as much information as possible about the nature of the epilepsy and the procedure planned, with clear outcome aims clarified with the family.

It is for this reason that a system of categorisation of epilepsy surgery on the basis of the probability of success has been proposed11. This would divide between those in which techniques and prognosis are well established (e.g. conventional temporal lobectomy and hemispherectomy for acquired lesions), those in which prognosis is not so clear-cut (e.g. extratemporal resections, hemispherectomy for developmental lesions, certain temporal lobectomies), and procedures performed on highly problematic individuals in whom surgical intervention may help (e.g. callosal section, subpial transection, trials of partial resection of abnormal tissue).
